Prosecutorial Discretion in Mutual Fund Settlement Negotiations, 2003-7

Eric Zitzewitz*

Dartmouth College

January 2009

Abstract

This paper examines the negotiated settlements of 20 market timing and late trading cases, comparing the restitution obtained for shareholders with an estimate of shareholder dilution. This restitution ratio varies from 0.04 to 5, or from 0.1 to 10 if penalties are included. While some of this variation is explained by differences in the defendants’ conduct, controlling for this, settlement negotiations that involved New York as well as the Security and Exchange Commission (SEC) resulted in restitution ratios that were higher by a factor of 5-10. An analysis that uses the firms’ headquarters location and customers’ state of residence as instruments for New York’s involvement suggests that this difference is causal, and not the result of New York involving itself in cases likely to lead to large settlements. Given the much larger staff and institutional expertise of the SEC, it is likely that these differences in outcomes are due to differences in effective aggressiveness, not prosecutorial resources. Differences in aggressiveness are consistent with popular conceptions of the regulators’ career concerns, as well as with theories of industry focus and regulatory capture.

The author would like to thank Cindy Alexander, Kenneth Arrow, Severin Borenstein, Jeremy Bulow, Elizabeth Casscio, John Chalmers, John Coffee, Stefano DellaVigna, David Dubofsky, James Freyer, Robert Hall, Eric Helland, Michael Herron, Michael Kremmer, Jon Reuter, Nancy Rose, Richard Ruback, Bruce Sacerdote, Richard Schmalensee, Carl Shapiro, Christopher Snyder, Steven Tadelis, Peter Tufano, Matthew White, Justin Wolfers, and seminar participants at Berkeley, Dartmouth, Stanford, the 2008 American Law and Economics Association meetings, the 2008 Claremont Securities Fraud Litigation conference, the 2009 ASSA meetings, and the 2008 IDC-Caesarea Center Finance conference for helpful discussions and comments. I also thank Charles Biderman of TrimTabs and Andrew Clark of Lipper for sharing data and for helpful conversations about their data. Over the last seven years, I have consulted, usually on a short-term basis, for many types of entities with an interest in these cases, including state and federal regulators, mutual fund firms, plaintiffs’ and defense attorneys, litigation consulting and accounting firms, and a fair value pricing service, and I have benefited from conversations with many anonymous individuals.
Prosecutorial Discretion in Mutual Fund Settlement Negotiations, 2003-7

I. Introduction

In the last half decade, the Security and Exchange Commission (SEC) has faced criticism that it has been excessively passive in addressing systematic problems such as conflicts of interest faced by analysts, asset managers, and rating agencies.1 Some have attributed this to capture by the industries it regulates, with a so-called “revolving door” staffing model for SEC attorneys cited as a root cause.2 Others though have argued that a desire to mitigate this impression of capture has actually led the SEC to become excessively aggressive itself in recent years (Macey, 2005), sometimes citing increases in the dollar value of penalties as evidence (Table 1). Ultimately, these claims are difficult for outsiders to evaluate since in most cases one is uncertain about what a regulator could have achieved given the evidence and resources available.

This paper studies a set of regulatory cases for which these problems are partially surmountable: twenty negotiated settlements of mutual fund market timing and late trading cases from 2003-7. Unlike most other securities regulation cases, in these cases the conduct at issue is relatively similar across cases and the harm to shareholders can be estimated using publicly available information. In particular, I calculate a restitution-to-harm ratio and restitution-plus-penalties-to-harm ratios for each settlement. Given the prosecutors stated objective of making affected shareholders whole, one would expect the

---

2 See, for example John Freeman’s (2004) Congressional Testimony, p. 1: “The SEC is MIA. … The SEC’s division of investment management (DIM) presents a classic case of ‘regulatory capture’. … And then there are the DIM alums. … My analysis of SEC personnel movements, using data I obtained from the SEC under FOIA, shows that most of the SEC’s senior personnel who leave the DIM go to work for mutual funds as officers or directors, for the ICI, or for service suppliers (law firms or accounting firms). … When I was working with the SEC in DIM years ago, I was told by a fellow staff lawyer: ‘Let’s face it, in five years we’ll all be working for these guys.’” See also Woodward (2001).
restitution ratio be at least one. In order to deter future violations, the restitution-plus-penalty ratio should be at least $1/p$, where $p$ is the ex ante probability that the conduct would be detected within the five-year statute of limitations (Becker, 1968).

The actual restitution ratios vary from 0.04 to 5, or from 0.1 to 10 including penalties. Proxies for ability to pay and the egregiousness of conduct explain only a small portion of the considerable variation in this ratio. In contrast, whether the New York Attorney General participated in the negotiations is strongly correlated with the restitution ratio. Of the 20 SEC-negotiated settlements in my sample, only four did not involve New York, but these four settlements included the first, second, and third-lowest restitution ratios. The dilution-weighted average restitution ratio is 0.07 for settlements that did not involve New York and 0.78 for the settlements that did.

This correlation between the restitution ratio and New York’s involvement, which persists when controlling for observable case characteristics, suggests two possible causal mechanisms: 1) New York’s involvement caused larger settlements or 2) New York’s probability of being involved in a case is correlated with unobserved factors leading to larger settlements. To attempt to distinguish between these mechanisms, I conduct an instrumental variables analysis using factors that affect New York’s likelihood of involvement but are plausibly uncorrelated with a case’s unobservable characteristics: whether a firm is headquartered in New York and the share of its single-state-municipal-bond-fund investors who are New York residents. The IV regressions provide statistically significant evidence of a causal effect and no evidence of a selection bias.4

---

3 The odds of 4 randomly selected settlements including the three lowest ratios are 1 in 285.
4 There is a substantial empirical criminology literature examining prosecutor and defendant race and gender in criminal cases (e.g., Paternoster, 1984; Radelet and Pierce, 1985; Schmidt and Steury, 1989); these studies are generally forced to assume that prosecutor identity is uncorrelated with unobservable case characteristics.
Why would New York’s involvement lead to bigger settlement amounts? Among state regulators, New York does have one of the tougher state "Blue Sky" anti-securities fraud laws (the 1921 Martin Act; see, e.g. Macey, 2005) and its Investor Protection Bureau is likely amongst the most sophisticated state regulators. But these cases all involved the SEC, which had both federal securities laws and its Enforcement Division (which has about 1,200 FTEs compared with 30 FTEs for New York's bureau) at its disposal. Therefore, New York's involvement is not likely to be contributing tougher laws or significant additional manpower. Instead, it is seems likely that the popular impression that New York pursues these cases more effectively and/or aggressively than the SEC is correct. A difference in effective aggressiveness could reflect under-aggressiveness on the part of the SEC, over-aggressiveness on the part of New York, or both. The fact that the average restitution ratio is less than 0.1 when the SEC negotiates without New York suggests the former. Restitution ratios of 2-5 for some of the cases involving New York suggest the latter.

This paper builds upon a recent report by the Government Accountability Office (2005). Cognizant of the newly large stakes involved in SEC settlement negotiations, in 2004 the Judiciary Committee of the U.S. House of Representatives commissioned a GAO review of the SEC’s restitution and penalty setting process. The GAO concluded

---

that “after the mutual fund trading abuses were uncovered in September 2003, SEC acted swiftly to bring enforcement actions against prominent firms and individuals involved in the misconduct and obtained some of its highest penalties in history from them in settlements. SEC has also consistently applied its procedures for establishing such penalties” (p. 32). At the same time, the GAO found that “SEC has not established controls that could help ensure the independence of staff from the fund industry as they carry out SEC’s critical oversight work,” noting that they did not monitor whether departing staffs’ future employment created a conflict of interest.

In June 2005, a Congressional hearing discussed the GAO report. In prepared testimony, it was noted that “while the GAO compares the size of the penalties to those in previous enforcement actions, an additional relevant comparison would be to the magnitude of shareholder dilution in each case” and that making this comparison would “inform the public’s evaluation of the fairness of the settlement process” (Zitzewitz, 2005a, 6). In post-hearing questioning, the SEC’s Division of Enforcement was asked to react to this statement. The SEC replied, in part:

In constructing a fair and appropriate settlement package, the securities laws afford the Commission the necessary flexibility to take a case-by-case view of the facts and circumstances of each case. … In the market timing cases, the Commission considers shareholder dilution, in itself one measure of shareholder harm, a factor in the consideration of disgorgement. … The Commission tends to refrain from identifying a single dilution figure in the public filings relating to the settlement of market timing cases, but rather focuses on the totality of the settlement package. …

Consideration of the magnitude of shareholder dilution allows for a wide range of estimates of dilution to fund shareholders by abusive trades which may be available for the Commission’s consideration at the time that a settlement is negotiated. This range is attributable to the many variables that may have an effect on the dollar value of particular
estimates of dilution. Variables include the overall method of estimation employed, the
time period used to encompass abusive trading that is subject to analysis, and the specific
trades during that period that are analyzed.6

While declining to provide the requested degree of transparency, the SEC quote is
useful in summarizing the reasons for which estimates of shareholder harm, and thus of
appropriate restitution, may differ depending on choices made when constructing them.
The SEC highlights three choices: the estimation method, the time period considered,
and the share of arbitrage trades within a time period that the fund company was held
responsible for. As I discuss in more detail below, the difference in settlements when
New York was involved can be partly explained by different choices along these three
dimensions.

The next section of the paper provides some background on the mutual fund
cases. The third section discusses methodologies for measuring shareholder dilution,
while the fourth section discusses the data I use, and my method for estimating dilution
using publicly available data. The fifth section calculates restitution ratios and examines
their empirical determinants. The sixth section discusses possible reasons New York’s
involvement might have affected settlement amounts. A discussion follows.

II. Background

The market timing and late trading cases analyzed in this paper involve instances in
which mutual fund management companies allowed favored shareholders to conduct
arbitrage trading at the expense of their shareholders in exchange for some economic

6 U.S. House of Representatives, Mutual Fund Trading Abuses: Hearing Before the Subcommittee on
Commercial and Administrative Law of the Committee on the Judiciary, p. 93 (available at
Arbitrage trading in open-end mutual funds exploits the fact that fund trades are priced using an accounting calculation, rather than a market-determined equilibrium price. Essentially all U.S.-based funds value their assets once per day at 4 PM Eastern Time and use these values to calculate a net asset value (NAV) per share. This NAV is used as the price for all purchase and redemption orders placed earlier in the day. Arbitrage trading is possible when the NAV calculation does not reflect information available to the arbitrageur at the time the trade is placed.

Market timing and late trading differ in the source of arbitrageurs’ advantage, as well as in their legality. Late trading cases involved trading decisions that were made after the 4 PM deadline but still received the current day’s price, in violation of the forward pricing rule (rule 22c-1, promulgated by the SEC in 1968). Late traders could earn abnormal returns by simply conditioning their trading on post-4 PM market movements. In many cases, late trading was conducted without the knowledge of the mutual fund company, often by brokerages that represented to fund companies that trading decisions had been made by investors before 4 PM, when in fact some investors had been given the opportunity to cancel orders after 4 PM. In other cases though, the fund management company was aware that investors were being allowed to late trade.

---

7 The overview in this section is brief and focused on regulatory cases, as much has already been written on market timing (also known as stale price arbitrage) and late trading. Bhragava, Bose, and Dubofsky (1998), Chalmers, Edelen, and Kadlec (2001), Goetzmann, Ivkovic, and Rouwenhorst (2001), Boudoukh, et. al. (2002), Greene and Hodges (2002), and Zitzewitz (2003) discuss market timing; Zitzewitz (2006) discusses late trading. Coffee (2003) and Mahoney (2004) place the issues within the broader context of manager-investor conflicts of interest.

8 See, for example, the cases against Security Trust Company (available at http://www.sec.gov/litigation/complaints/comp18479.pdf) or Bear Stearns (http://www.sec.gov/litigation/admin/33-8668.pdf).

9 In November, SEC Enforcement Director Steven Cutler (2003, 16) testified before Congress that a SEC questionnaire had revealed that over 10 percent of 88 large fund families had been aware of late trading in their funds.
These latter cases were regarded as particularly egregious by regulators, and I find that they involved higher restitution and penalty ratios.

Market timing (also known as stale price arbitrage) trades are made before 4 PM, but exploit the fact that many fund companies use NAV calculation methods that misvalue fund shares by under reflecting recent market movements. NAVs can under-reflect recent market movements for two reasons: time zones and illiquidity. International mutual funds usually hold assets that trade on exchanges located in other time zones that close before 4 PM ET. Most mutual funds have historically valued these assets using these foreign closing prices, which do not reflect global market movements between the foreign close and 4 PM. In addition, securities that trade illiquidity often have last trade prices or bid and ask quotes that do not reflect recent market movements (Lo and MacKinlay, 1990; Kadlec and Patterson, 1999; Blume and Keim, 2006). This causes the NAVs of fund in asset classes such as small-cap equities and high-yield and municipal bonds to lag market movements. Zitzewitz (2003, Table 4) reports that in 2001, time zone arbitrage in international and global funds accounted for about 90 percent of the adverse impact on fund shareholders, with liquidity arbitrage in small and midcap domestic equity funds accounting for most of the remainder.

Unlike late trading, pre-4 PM trading to exploit inefficiencies in mutual fund valuation is not illegal *per se*. The legal issues for mutual fund companies arise from the fact that they both chose to price funds using methods that misvalued fund shares and simultaneously earned private benefits from allowing certain arbitrageurs to exploit these misvaluations. As Zitzewitz (2003) discusses, the mutual fund industry has been aware of time zone-related valuation issues for at least 25 years. Its approach, initially
sanctioned by the SEC in the form of a 1981 no-action letter to Putnam Investments, has historically been to calculate fund NAVs using foreign local closing prices on most days, but to update those prices through a process known as fair value pricing on days with especially large post-close market movements. In December 1999 and again in April 2001, however, the SEC recommended far more frequent use of fair value pricing.\textsuperscript{10} Despite this, fair value pricing was still used only infrequently by most firms before the regulatory investigations began in mid-2003 (Zitzewitz 2003 and 2005b).

Regulatory investigations later revealed that many mutual fund firms had benefited from the inefficient pricing of their fund shares by essentially selling the right to conduct large-scale arbitrage trading to favored investors. Favored investors usually paid for the right to arbitrage trade by investing so-called “sticky assets” in high-fee money market or hedge funds run by the mutual fund manager. Some of the mutual funds involved had trading fees from which favored investors were exempted, while others represented to investors in their prospectus that they would limit all investors to a certain number of trades per year and then selectively did not enforce this limit. In three instances, either the chairman of the fund management company or a group of portfolio managers allegedly engaged in arbitrage trading of their own funds. Like the cases in which late trading was knowingly allowed, this was regarded as particularly egregious by the regulators, and I find that these cases likewise involved higher restitution and penalty ratios.

As a means of diverting fund shareholder assets for the private benefit of the management company, misvaluing funds and then selling the right to conduct arbitrage

was inefficient for two reasons. The first was that the management company was usually not able to extract the full value of the arbitrage opportunity from a paying arbitrageur. The second was that misvaluing fund shares created arbitrage opportunities for investors who did not pay for them, since fund companies could not completely exclude non-paying arbitrageurs. A crucial issue in calculating restitution is whether a fund company that misvalued fund shares and sold the right to conduct arbitrage is responsible for all of the economic harm arising from the misvaluation or for only for the dilution caused by shareholders who paid. When the SEC refers above to “the specific trades analyzed” as an important determinant of a dilution calculation, it is in large part referring to this choice.

III. Measuring Dilution

As the SEC quote above alludes to, the “method of estimation employed” can significantly affect the measurement of the dilution of long-term shareholders due to arbitrage trading. While I will use multiple methods in the analysis and while my conclusions about the effect of New York’s involvement are robust to the choice of method, the method chosen does affect conclusions about the overall level of reimbursement ratios, and discussing how and why the methods differ gives some insight into the scope for prosecutorial discretion in these cases.

Broadly, there are two methods for measuring dilution. The first was developed in the pre-scandal academic literature on stale price arbitrage and late trading, which I will refer to as the “academic method.” There are two versions of the academic method, but they yield highly correlated results in most samples. The first version, used by
Goetzmann, Ivkovic, and Rouwenhorst (2001) (GIR) and Zitzewitz (2003), measures dilution resulting from traders purchasing (selling) fund shares for less (more) than their current value. This is given by:

\[ \sum_t \Delta shares_t \cdot (NAV_{t}^{FV} - NAV_{t}^{Actual}) , \]  

where \( NAV_{t}^{FV} \) is the value of the fund shares at the time the trading decision is made, which is usually assumed to be 4 PM, or a later time for a potentially late trade. (1) is equivalent to the difference between the assets of the fund and what they would have been had the transactions been handled at fair value NAVs. The second version, used by Greene and Hodges (2002), captures the difference between the net cash injected into a fund by traders and what would have been injected had their trades been delayed until the next day:

\[ \sum_t \Delta shares_t \cdot (NAV_{t+1}^{Actual} - NAV_{t}^{Actual}) . \]

While the counterfactuals considered by the two versions are different, they usually yield similar results. If a fair value NAV is defined as the expectation of the next-day NAV given information available at 4 PM, then the difference between the two versions is the sum of net share purchases times the unexpected NAV change. So long as fund share trading is not conditioning on post-4 PM information, then this difference should be zero in expectation. The first (GIR-Z) version therefore yields a measure of dilution that varies less across time depending on whether post-4 PM market movements turned out to be advantageous for fund traders. On the other hand, the second (GH) version incorporates any late trading that conditioned on post-4 PM information, as well as any information that was available at 4 PM but omitted by the econometrician when constructing fair value NAVs.
The second, or “consulting”, method was developed by Ciccotello and Greene (2006) and other expert witnesses as part of post-investigation consulting work. In addition to considering dilution from arbitrageurs trading at stale NAVs, the consulting method also considers the impact of arbitrageurs' flows on the portfolio of the fund. It is often implemented in practice by assuming that the proceeds from purchases from known short-term traders were held in cash and that this increased the cash holdings of the fund dollar-for-dollar. In periods of declining markets, such as the 2001 to early 2003 period in which much of the fund arbitrage covered by the cases occurred, increasing the cash content of a portfolio turned out to be helpful, at least ex post. The consulting method differs from the academic method in giving fund management companies credit for this presumed effect of arbitrage trading in increasing their cash holdings.

For example, suppose a short-term trader purchased a single fund share on day $t$ and sold it on day $t+s$. The Greene and Hodges version of the academic method would calculate dilution from this transaction as

$$ (\text{NAV}_{t+1}^{\text{Actual}} - \text{NAV}^{Actual}_t) - (\text{NAV}_{t+s+1}^{Actual} - \text{NAV}^{Actual}_{t+s}) $$

whereas the consulting method would calculate it as:

$$ (\text{NAV}^{Actual}_{t+s} - \text{NAV}^{Actual}_t) - \text{NAV}^{Actual}_t \cdot [(1 - \lambda) \cdot r^{\text{Cash}} \cdot s + \lambda \cdot (r_{t+1:t+s+1}^{\text{Port}})] $$

where the first term is the difference between the cash paid and received by the trader, and the second term is the return earned by the fund using the trader’s money, assuming that a $\lambda$ share is invested in assets normally held by the fund and the remainder is held in cash. If $\lambda = 1$ and $r_{t+1:t+s+1}^{\text{Port}} = (\text{NAV}^{Actual}_{t+s+1} - \text{NAV}^{Actual}_{t+1}) / \text{NAV}^{Actual}_t$, then the two methods will yield the same result. If $\lambda < 1$ and the mutual fund’s asset class underperformed cash ($r^{\text{Cash}} \cdot s > r_{t+1:t+s+1}^{\text{Port}}$), then the consulting method will yield a lower result. If $\lambda = 0$, then
(4) equals the cash profits of the short-term trader. When dilution of shareholders and
short-term trader profits are discussed as if they are identical, this is usually an indication
that the consulting method is being employed with $\lambda = 0$.\textsuperscript{11}

Whether one should credit a defendant for allowing arbitrage trading that ended
up forcing it to hold more cash than it normally would have given its investment
objective is debatable. Even if one accepts that one should, however, determining the
effect of short-term trading on a portfolio’s average cash position is far from
straightforward. A reasonable theoretical model of the issue would be to assume that
portfolio managers have an optimal percentage cash holding $c^*$ and face convex losses
$l(c-c^*)$ from deviations on either side. If this loss function is quadratic, the manager will
target an average cash holding of $c^*$. For example, faced with a short-term trader whose
money was in the fund on 50 percent of days, a manager who wanted to avoid
incremental security trades would respond by targeting cash holdings of $c^* - \frac{x}{2}$ on days
the short-term trader was out of the fund and $c^* + \frac{x}{2}$ on days she was in the fund, and
the presence of the short term trader would not affect the average cash holdings of the
fund.\textsuperscript{12} So long as $l'$ is not infinite below $c^*$ or zero above $c^*$, managers should respond
to a short-term trader by holding more cash when she is in the fund and less cash when

\textsuperscript{11} For example, in a frequently asked questions memo regarding its settlement with regulators, Waddell
and Reed states, “as the Kansas Securities Commissioner’s order recognizes, market timing can actually
benefit a fund during a declining market. This is borne out by the fact that one of the market timers who
paid service fees to Waddell & Reed actually lost more than $6 million while trying to time the funds.
Nonetheless, the SEC ultimately determined that investors in aggregate profited from timing the fund and
that such profits diluted the funds.” Waddell and Reed, Memo, July 2006, 2 (http://media.corporate-

\textsuperscript{12} In this specific example, with a short-term trader who is in the fund 50 percent of the time, it is sufficient
for the loss function to be symmetric for the manager to target $c^*$. 

13
she is out of the fund. The consulting method ignores the latter effect, suggesting that it should overstate the effect of short-term trading on a fund’s average cash holdings.\textsuperscript{13}

Indeed, an empirical analysis reveals that funds experiencing heavy short-term trading had average cash holdings that were no higher than other funds, consistent with what one would have expected from the analysis above but inconsistent with the implicit assumptions of the consulting method. Regressions in Table 2 examine the correlation between short-term trading activity, as measured by fund share turnover, and both the average cash holdings and average betas of international funds.\textsuperscript{14} It finds no evidence of the positive correlation between short-term trading and either cash holdings or betas that is often assumed by the consulting method, whether or not other variables that might influence average cash holdings are controlled for. The coefficients and standard errors imply that the upper limit of the 95 percent confidence interval equates to a 100 percent increase in fund share turnover being associated with a 12 basis point increase in the share of the portfolio held in cash or a beta that is 0.002 higher, so an economically meaningful positive correlation can be ruled out.

For comparison, the Table also presents identical regressions with returns as the dependent variable. In contrast to the lack of a relationship with cash holdings, fund share turnover is strongly negatively related to returns: 100 percent higher fund share turnover is associated with returns that are 13 basis points lower. This relationship is of

\textsuperscript{13} Even when the consulting method analyzes whether incremental short-term money was invested or held in cash, it assumes that funds did not target a lower cash holding when the short-term money was out of the fund. See, for example, Hamermesh (2006, p. 4): “For any given mutual fund, if the funds a timer uses to purchase fund shares were never invested in risky portfolio assets by the portfolio manager, timer net gains would accurately measure dilution to contemporaneous shareholders. To the extent, however, that timer funds were invested in risky assets, dilution may diverge from timer net gains. Accordingly, it is necessary to estimate the extent to which portfolio managers invested in (and sold) portfolio assets in response to timer investment (and sales).”

\textsuperscript{14} Cash holdings data are taken from CRSP, but results are virtually identical if one uses cash holdings data from Morningstar CDs.
essentially identical magnitude in years with rising and declining markets, casting further
doubt on the idea that arbitrage trading helps funds in down markets by increasing cash
holdings.

IV. Constructing fund-level dilution estimates from publicly available data

Given this background, I shall proceed by calculating dilution using four different
methods: the GH and GIR-Z versions of the academic method and two versions of the
consulting method, one that assumes portfolio managers target a given average cash
balance, and one that assumes managers target a minimum cash balance. The GH
method is implemented as described in that paper. The GIR-Z method requires
estimation of a fair value NAV, which is done assuming a transaction time of 9 PM as in
Zitzewitz (2006) to take account of dilution due to any late trading. As in Zitzewitz
(2003), Tufano (2005), and Zitzewitz (2006), a portfolio-level fair value NAV is
estimated by regressing NAV returns on four predictive factors: the difference between
the Chicago Mercantile Exchange Nikkei 225 future price at 4 PM Eastern time and the
closing Nikkei futures price from the Singapore Exchange and S&P future returns from 3
to 11:30 AM, 11:30 AM to 4 PM, and 4 PM to 9 PM.15 To avoid a data-snooping bias,
the weights on these factors are estimated for each day using a rolling one-year window
of prior data and then applied out of sample to the factor returns from that day. This
methodology approximates that of commercial fair value pricing services that since 2003
have been increasingly used to value international equities.16

15 The breakpoints for S&P futures changes are chosen to capture the approximate capitalization-weighted
average closing time of Asian markets (3 AM), European markets (11:30 AM), U.S. equity markets (4
PM), and the latest time that late trades have been reported being placed (9 PM).
16 See, for example, U.S. Patent No. 7167837, “Fair Value Pricing of a Financial Asset.”
The consulting method requires estimating the fund share holdings of short-term traders and then making an assumption about how the portfolio manager reacts to these holdings when setting cash holdings. I approximate short-term trader holdings as the difference between the number of fund shares outstanding (adjusted for reinvestments of distributions) on day \( t \) and the minimum number of shares outstanding in the prior 20 trading days.\(^{17}\) For manager responses to short-term traders, I make two relatively extreme assumptions in the hope that they bound the truth. First, in the “min cash target” version, I assume that the cost to a manager of being below her target cash holdings are infinite, and thus managers target a minimum cash holding and hold all short-term trader funds in cash. Second, in the “mean cash target” version, I assume that managers target an average daily holding, so short-term trading leads does not lead to an increase in average cash holdings.\(^{18}\) The first assumption is more consistent with how the consulting method is often implemented in practice, while the second assumption is more consistent with the lack of a correlation between fund share trading and cash holdings reported in Table 2.

Table 3 reports estimates of asset-weighted average annualized dilution rates for international equity funds by year, constructed using each of the four methods. Whereas

\(^{17}\) For funds I have analyzed where I do have account-level data, this method has performed well in approximating the results of direct measurement of the holdings of short-term traders. One shortcoming of this method is that when a fund is growing, the method will incorrectly label some of the additional assets as short-term trader assets. On the other hand, it likely that a manager might not know the intentions of every trader that purchases his fund, and thus might face the same uncertainty. An alternative method, which assumes perfect foresight of shareholder holding periods by managers and measures short-term trader holdings as the difference between shares outstanding on day \( t \) and the higher of 1) the lowest shares outstanding from the prior 20 days and 2) the lowest shares outstanding from the next 20 days, yields average short-term trader holdings that are about half as large as with the no-foresight method. Given this, the no-foresight method probably overstates short-term trader holdings, and thus overstates any impact they would have on the cash holdings of a fund.

\(^{18}\) Specifically, I assume that the difference between the shares outstanding on day \( t \) and the difference between the average number of share outstanding of the last 20 days is held as extra cash. This implies that a fund will hold more cash when short-term traders have recently bought the fund and less cash when they have recently sold.
most of this study will focus on the 2000-3 period emphasized by the regulators, in order to examine the effect of the general direction of the market on dilution estimates, in this table I include the up-market years 1998-9. While estimates constructed using both versions of the academic method are fairly consistent regardless of the general direction of the market, the consulting method yields higher dilution estimates during the up market of 1998-99 and lower dilution estimates during the down market of 2001-3. As one would expect, the “min cash target” version of the consulting method, which assumes that short-term money increases the cash holdings of the fund, yields dilution estimates that are the most affected by the direction of the market. Indeed for small-cap equity funds (omitted in Table 3), the “min cash target” method actually yields negative dilution estimates for 2001-3. In contrast, the “mean cash target” version yields results that are more consistent with the academic methods.

All of these methods for measuring dilution require fund-level daily flow data, which are not publicly available. Past work on dilution uses proprietary daily fund flow data for a sample of funds and extrapolates from the sample to the industry as a whole (GIR, 2001; Greene and Hodges, 2002; Zitzewitz, 2003; Zitzewitz, 2006). The focus on industry-level dilution allows this work to avoid discussing observations for particular fund families.

This paper, in contrast, requires estimating family-level dilution for comparison with settlement amounts, including fund families that are not included in the sample, and so I must take a different approach. I exploit the relatively close correlation between publicly available data on fund share turnover and dilution. For each category of fund

---

19 My two sources of data asset data are Lipper (March 2000 to December 2003) and TrimTabs (February 1998 to December 2003). For consistency between years in Table 3, I use only the TrimTabs data. Adding the Lipper data after March 2000 does not significantly affect results, however.
and each year (e.g., Asia/Japan) and each year, I estimate the relationship between fund share turnover and dilution, using the data for the sample of funds for which I have daily flow data from data flow data provided to me by Lipper and Trim Tabs (this joint Lipper and Trim Tabs sample is also used in Zitzewitz, 2006). I then use these relationships to generate predicted dilution rates for every fund, using the fund’s publicly reported fund share turnover. This approach therefore utilizes individual funds’ daily flow data only to estimate the overall dilution-turnover relationship, and these data are not used in the dilution estimates for any given fund family.

The procedure starts by matching gross fund share sales and redemption by fund and fiscal year for 2000 to 2003 to either average daily asset data from Lipper or average month-end asset data from CRSP (in order of priority) using ticker symbols. Fund share turnover can thus be calculated for every fund with a ticker symbol for which Lipper collected gross sales and redemption data from the original SEC filings. The second step is to use the combined Lipper and Trim Tabs daily flow data (described in more detail in Zitzewitz, 2006) to estimate dilution rates for fund*fiscal year combinations and to match these dilution rates with the fund turnover rates. Predicted dilution rates are then estimated from fund share turnover rates using the semi-parametric method described below, and predicted dilution is then summed across a company’s funds to yield a company-level measure. The process is repeated for each of the four dilution measurement methods discussed above (i.e., the GIR-Z and GH versions of the academic method, and the consulting method assuming that managers target minimum or average cash holdings).
Table 4 reports summary statistics for the sample of international equity funds in CRSP, for the subset of these which can be matched with Lipper fund share turnover data, and for the smaller subset for which daily flow data is also available. An observation is a fund*fiscal year. Given that most funds have fiscal years that end in months other than December (October is the most common), the annual variables taken from CRSP (expense ratios, loads, portfolio turnover, cash holdings) are from the prior calendar year. Average month-end assets are calculated using the data for the exact months of the funds’ fiscal year. Fund share turnover data is available for 57 percent of fund*years and 80 percent of assets; about 62 percent of these observations (and 38 percent of these assets) also have daily flow data that allows the calculation of dilution rates. Fund share turnover is calculated as the minimum of sales and redemptions divided by average month end assets.\textsuperscript{20} As others have noted (e.g. Greene and Hodges, 2002), the ultimate source for the sales and redemption data, Form N-SAR filings, often include figures that are off by 3 orders of magnitude due to filers entering figures as whole dollars or millions instead of thousands. This results in some obvious outliers; to limit their impact, I treat observations with fund share turnovers below 0.1 or above 50 as missing.\textsuperscript{21}

A comparison of the difference between the equal and asset-weighted averages reveals that fund share turnover and dilution are negatively correlated with fund size. Apart from differences in average fund size, the sample of funds with share turnover

\textsuperscript{20} An alternative would be to divide the average of fund share sales and redemptions by average assets, which would yield a higher measure for a fund that was growing or shrinking over the course of the year. I use the minimum of sales and redemptions as it yields a slight better predictor of fund share trading that is correlated with NAV predictability and thus produces dilution.

\textsuperscript{21} These cutoffs are arbitrary, but results are not very sensitive to them. It should be noted that when average daily assets are used as the denominator, the maximum possible fund share turnover in a typical year with 252 trading days is 126, assuming T+1 settlement of fund shares.
information is roughly representative of the broader sample, as is the subset of those funds with daily flow data. The equal-weighted average fund share turnover rates and dilution rates are about 2.5 and 1.5 percent for this latter subsample, respectively. The ratio of these two is informative about the extent to which trading in the fund was opportunistically timed. A fund share turnover ratio of 2.5 implies that a fund with a $100 in average daily assets would have experienced at least $250 each in fund share sales and redemptions in over the course of a year (compared with $66 for non-international funds). Dilution of 1.5 percent implies that these $250 in roundtrip trades were accompanied by $1.50 in dilution, or about 0.6 percent of the roundtrip trading volume. This could have resulted, for example, from these roundtrip trades involving purchases when the fund was underpriced by 0.3 percent and sales when it was overpriced by an equivalent amount.

Table 5 examines the relationship between fund share turnover and dilution in more detail. Fund*years are divided into cells based on their amount of fund share turnover and their rough asset class.\textsuperscript{22} Average dilution is clearly increasing in fund share turnover. In addition, the regionally focused European and Asian stock funds experience more dilution and more dilution for a given fund share turnover rate than general international and emerging market equity funds, which in turn experience more dilution than global or domestic small and midcap equity.\textsuperscript{23} Given this, when econometrically estimating the relationship between share turnover and dilution, I will separate domestic

\textsuperscript{22} I classify funds by asset class using information, in order of priority, from Lipper, Morningstar (matched by ticker), and CRSP (matched by ticker). In Table 5, the categories for Asian Stock funds, Japan Stock funds, Chinese stock funds, and Pacific (x. Japan) stock funds are aggregated, as are the categories for global and Latin American equity (which have similar dilution levels).

\textsuperscript{23} As Zitzewitz (2003) discusses, these funds attracted more arbitrage trading because trading one of either Europe or Asia offered more arbitrage profits than trading a fund that was a combination of the two.
Table 6 presents regressions that use fund share turnover to predict dilution. In Panel A, average turnover rates, dilution rates, and their ratio are reported for diversified and regionally focused funds for different levels of share turnover. In panel A, it appears that funds with low fund share turnover rates also have, understandably, very low dilution. Dilution rises more or less linearly with fund share turnover, although the dilution-turnover ratio does appear to be maximized at intermediate levels of dilution.

Given the approximate linearity of the relationship, I first estimate an asset-weighted linear predictive model. This appears to estimate negative dilution for funds with very low turnover rates, which is undesirable, so I instead estimate linear spline models, with the kinks at the 20th, 40th, 60th, and 80th percentile of the overall fund share turnover rate distribution. These models offer a modest improvement in R-squared.

In the analysis that follows in the rest of the paper, I estimate the spline regressions separately for each year and for each of the four dilution methodologies, and I construct a predicted dilution rate for each fund*year for which I have fund share turnover data. For the fund*years where I lack this data, I assume a dilution rate equal to the asset-weighted average for that year and asset class. I then add dilution across a mutual fund companies’ funds to construct an estimate of fund-family dilution for the fiscal years 2000-3 period. It is this sum that I compare with reimbursements and penalties to evaluate the outcome of settlement negotiations.
V. Analysis of the Settlements

Table 7 provides data on the 20 settlements of market timing and late trading cases negotiated with mutual fund families as of January 2007. Most settlements were negotiated in 2004. The settlements usually involved simultaneously announced settlements of federal and state regulatory investigations. Sixteen of the 20 settlements involved the state of New York, and seven of those involved another state as well. All settlements included a restitution component, and 18 of the 20 included a penalty as well. Once restitution and penalties are agreed upon, they are distributed to affected shareholders according to a plan developed by an Independent Distribution Consultant (IDC), an expert who is selected by the board of the affected funds and whose choice must be approved by the regulators.

In addition to restitution and penalties, the New York Attorney General also negotiated future fee reductions as part of 12 of the settlements. The SEC has taken the position that it should not regulate mutual fund fees and thus, while most aspects of the settlements have been coordinated between the SEC and the states, the SEC has explicitly noted that it did not participate in the fee negotiation part of the settlements. Determining the extent to which a fund company that is forced to reduce its fees has been punished is, of course, quite complicated. For simplicity, I will simply ignore the fee reduction component of the settlement and simply analyze restitution and penalties. Since only

---

24 The regulators have also brought cases against brokers and hedge funds, for example, for falsifying records and engaging in late trading. Since the dilution from these cases occurred in multiple families’ funds, I cannot construct a dilution estimate for each settlement and therefore omit them from my analysis.

25 One issue is that if fees begin at a profit-maximizing level, then, at that level, the derivative of profits with respect to fees should be zero and thus the first increment of fee reduction should not be costly at all. In addition, if fund firms are tacitly colluding, a regulator-mandated fee reduction may benefit a fund firm by allowing it means of reducing price without generating a competitive response.
New York insisted on fee reductions, excluding them will tend to make New York-negotiated settlements appear smaller.

Table 8 compares the settlement amounts to my estimates of family-level dilution for the fiscal years ended 2000-3, as well as to other measures of economic size and trading activity. The restitution-to-estimated dilution ratio ranges from 0.04 to 5; the four settlements not involving New York include the first, second, and third-lowest ratios. Restitution-to-dilution ratios are very similar to ratios with alternative denominators, either total mutual fund assets, international equity fund assets, or the latter multiplied by average fund share turnover rate, foreshadowing the fact that conclusions about an “Eliot effect” are not very sensitive to the method used to measuring dilution. The average estimated dilution rate (using the GIR-Z version of the academic method) is reported; it is understandably higher for families with a higher average fund share turnover rate and for families with a higher proportion of regionally-focused funds.

Table 9 presents regressions that seek to econometrically explain the variation in restitution ratios. The log restitution ratio (with and without penalties) is regressed on variables capturing the severity of conduct, the involvement of New York state, and the fund firm’s ability to pay. The regressions higher ratios for cases that involved late trading or where senior managers were alleged to have conducted arbitrage trading in their own funds, but neither difference is statistically significant. Ratios are (statistically and economically) significantly higher in cases involving New York by between 1.2 and 2.1 log orders of magnitude (i.e. by a factor of between 3.3 and 8.4). Regressions that test whether settlements involving only New York differed from those involving New York and other states find no significant differences. Adding a proxy for ability to pay, the
fund family’s log mutual fund assets at the end of 2003, does not affect results. The constant in all but the last two regressions has a natural economic interpretation as the log restitution ratio for cases that do not involve late trading, senior manager trading, and/or New York. When the null hypothesis of a zero constant is rejected, this is equivalent to rejecting the hypothesis that the restitution ratio in these cases was one.

Table 10 presents instrumental variables (IV) regressions aimed at testing whether the correlation between restitution ratios and New York’s involvement reflects a causal effect. In this context, a valid instrument would be a variable that affects the likelihood that New York would become involved in a case, but is uncorrelated with any unobserved factor affecting the restitution ratio, such as the severity of conduct. State regulators generally have a rationale for involving themselves in a securities case to the extent that the conduct in question took place in their state or to the extent that residents of their state were harmed by it. This suggests two possible instruments for New York’s involvement: whether a fund firm is headquartered in New York and the share of its investors who are New York residents. The identifying assumption involved in using these instruments would be that mutual fund firms that are headquartered in New York or have more New York resident customers, did not have higher settlement amounts for unobserved reasons, such as having engaged in more egregious conduct or having less bargaining power when negotiating with regulators.26

---

26 The anecdotal evidence I have been able to obtain about why New York was not involved in the four settlements (Putnam, Pimco, American Express Financial Advisors, and Franklin) is largely consistent with headquarters location being important. The Putnam case arose from a Massachusetts-resident internal whistleblower who contacted the Massachusetts regulators. In the Pimco and American Express cases, I have been told that New York did not participate because there were home-state regulators who wanted to play a lead role on a case. Franklin (a California-headquartered firm whose settlement involved Massachusetts) is the exception where state headquarters does not appear to have played a role.
Table 10 presents first-stage, reduced form, OLS, and IV regressions. The proportion of mutual fund investors who are New York residents is not publicly available, so I use as a proxy the share of a fund family’s single-state municipal bond fund assets accounted for by New York.\(^{27}\) The first-stage regression reveals that settlements with fund families with a higher share of New York investors and with headquarters in New York were more likely to involve the New York Attorney General.\(^{28}\) A comparison of the OLS and IV coefficients on New York involvement reveals that the latter are modestly larger, although Hausman tests do not reject the hypothesis that they are the same. Using only the municipal bond instrumental variables yields results that lose statistical (but not economic) significance; a test of the overidentifying restriction does not reject, suggesting that headquarters location is not endogenous. Using the New York headquarters instrument alone unfortunately does not yield precisely estimated coefficients.

Instrumental variables suffers from known small-sample biases (Nagar, 1959). Supplementary evidence is available from the reduced form regressions, which reveal that firms headquartered in New York and with a high share of New York single-state muni bond shareholders paid significantly higher restitution ratios (differences in ratios that include penalties are about half as large and are not statistically significant). In addition, of the 326 fund firms offering international, global, or small-cap funds, firms with more New York muni shareholders are more likely to have been among the 20

\(^{27}\) Single-state municipal bond funds hold municipal bonds issued by a particular state. They generally offer lower yields than other municipal bond funds, but are attractive to residents of that state because their interest is deductible from that state’s income tax. For fund families that offer no single-state muni bond funds, I code the New York percentage variable as zero and the “no single state muni funds” variable as one.

\(^{28}\) I follow Angrist and Krueger’s (2001) advice and use a linear probability model for the first stage.
involved in settlements, both with and without controlling for shareholder dilution and family size. Taken together, the regressions in Table 10 imply that firms with greater exposure to New York state regulation (via their headquarters or location or customer base) were more likely to be involved in a regulatory case, were more likely to have New York involved in negotiations, and paid higher restitution ratios.

Table 11 presents some alternative dilution measures and specifications as robustness checks. For international and global equity funds, switching dilution measurement methods does not affect one's conclusions about the effect of New York’s involvement in settlements.\(^{29}\) One might have expected regulators to negotiate settlements in cases with the worst conduct first, to obtain higher restitution ratios in these cases, and for New York to have been more likely to have been involved in these cases. Adding controls for settlement timing and a dummy for whether the settlement was announced after Christopher Cox replaced William Donaldson as SEC chairman does little to affect the coefficient on New York’s involvement, however. Likewise, dropping the Alger settlement, which was announced two weeks after Andrew Cuomo replaced Eliot Spitzer as New York attorney general, does not meaningfully affect the results.

Table 11 also considers the robustness of the results to alternative interpretations of circumstances surrounding the settlements. Two of the settlements, those with Bank of America and Fleet, were negotiated while the two firms were conducting merger talks. The time pressure created by an impending merger might have increased regulators’ bargaining power. In addition, Bank of America was also accused of facilitating late

\(^{29}\) The downward bias of the consulting method in down markets is large enough that including small cap equity funds leads the “min cash target” version of the method to produce negative dilution estimates for 17 of the 20 settlements. Since a restitution ratio with a negative denominator is difficult to interpret, I exclude small cap equity funds from the analysis of robustness to method.
trading as a broker in addition to as a fund company, and so the settlement might have been larger because it covered that alleged behavior as well. Although these two settlements had among the higher restitutions ratios and involved New York, excluding them does not materially affect the New York involvement coefficient.

A second issue is which amount to use for the settlement with Putnam. The Putnam settlement was unique in that the restitution amount was a minimum that could be subsequently adjusted upward if the IDC found that actual harm to shareholders had been higher.\textsuperscript{30} As it turned out, in his report as Putnam IDC, Peter Tufano (2005) concluded that Putnam shareholders had been harmed not only by the direct dilution from employee trading, but also from the price impact caused by sales that were forced when customers withdrew funds after the scandal was revealed. This caused the restitution amount for the Putnam settlement to be adjusted from $10 million to $93 million. Given that this upward revision was likely not anticipated at the time the settlement was negotiated, I have decided not to include it in my central results, but do include an alternative version of the results in Table 10 that uses the revised restitution amount for the Putnam settlement. Adjusting the Putnam restitution amount does lower the New York involvement coefficient, especially for restitution, but it remains statistically and economically significant. As a final robustness check in Table 11, I dilution-weight rather than equal-weight the settlements. Doing so significantly increases the estimated magnitude and precision of the constant and New York involvement coefficients, and also yields $F$ and $R^2$ statistics that suggest a tighter regression fit. All of the results

\textsuperscript{30} In the other 19 settlements, the IDCs did not play a role in determining the settlement amount, but rather developed the plan for apportioning the settlement among affected shareholders.
presented thus far in the paper are significantly stronger if observations are dilution weighted.

As Hogue and Wellman (2005), Choi and Kahan (2006), and Schwarz and Potter (2006) have shown, mutual fund firms involved in regulatory cases experienced “market penalties” as well as regulatory ones. Table 12 compares the restitution and penalties imposed by regulators with the effect on firm value of business lost after the cases were announced. I follow Choi and Kahan (2006) and estimate the lost business penalty associated with a regulatory case by comparing the actual assets of a family’s mutual surviving funds 12 months after announcement with what their assets would have been had their funds received the asset-weight average percentage inflow for their categories (defined using S&P objective codes). The average settlement firm suffered a lost business penalty of over 10 percent of assets; penalties were especially high for Invesco (40 percent), Strong (32 percent), Putnam (30 percent), and Janus (28 percent).

If I value their lost assets using the approximate average valuation multiple of 4 percent from mutual fund acquisitions (Pozen, 2002; Huberman, 2006), I find that total lost business penalties ($6.8 billion) were larger than the total penalties and restitution in the settlements ($2.4 billion). Adding lost business effects brings the total punishment-to-harm ratio above 1.0 for 17 of the 20 settlements. This is significant, given that a ratio of at least $I/p$, where $p \leq I$ is the probability within the statue of limitations, is likely necessary for deterrence (Becker, 1968).

---

31 Choi and Kahan (2006) value lost assets at one year’s expense ratio revenue and conclude that they were smaller than the regulatory penalties. For data availability reasons, Hogue and Wellman (2005), Choi and Kahan (2006), and I are unable to calculate the “inflow penalty” suffered by the firms in their other business lines (e.g., pension or hedge fund management, brokerage). Anecdotal evidence from news reports suggests that business losses in these other product lines were also significant.
That said, lost business penalties vary considerably. Firms who received prosecutorial and media attention earlier in the scandal suffered much greater market penalties for a given amount of shareholder harm, and the ratio of lost business penalty shareholder harm varies even more than restitution ratios. and do not appear to be systematically related to the severity of conduct. Including outflow penalties in restitution+penalty ratio significantly raises the average ratio, but does not change one’s conclusion that penalties were higher in cases involving New York.

VI. Why an Eliot (or New York) Effect?

Taken together, these results suggest that New York’s involvement had a significant effect on the outcome of settlement negotiations. When New York was involved, the dilution-weighted average restitution ratio was 0.77, when it was not involved, the average was 0.07. Including penalties, the corresponding averages were 1.25 and 0.25. What can account for this large a difference?

In explaining its reluctance to compare settlement amounts to family-level estimates of dilution to the House Judiciary Committee as quoted above, the SEC cited three reasons why estimates of dilution may differ: 1) the “method of estimation employed”, 2) “the time period”, and 3) “the specific trades during that period that are analyzed.” While the robustness checks in Table 11 suggest that the overall method chosen does not significantly influence conclusions about the effect of New York’s involvement, Table 3 illustrates an important interaction effect between time period and method.
As discussed in the previous section, the primary difference between the consulting and academic methods is that the former includes the effect of short-term trading on portfolio composition. In practice, this is often done by assuming that fund managers hold all investments from short-term traders are in cash and thus short-term trading increases the cash holdings of the fund. Ex post, holding more cash turns out to be a benefit in down markets, and thus the version of the consulting method that assumes managers target minimum cash holdings tends to yield lower estimates of dilution in down markets.

Thus one plausible partial explanation for the settlement outcome differences would be if the SEC focused attention on the downward market period of 2001-3 and favored the “min cash target” consulting methodology when setting settlement amounts. A second plausible explanation would be if New York and the SEC differed in the proportion of trades they held fund companies responsible for. Many of the SEC releases that accompanied settlements refer to the specific amount of dilution arising from favored arbitrageurs, and none that I have seen refer to the overall amount of dilution in the funds arising from a failure to fair value price. If New York considers the overall level of dilution when negotiating settlement amounts, while the SEC considered only the dilution from the favored subset of arbitrageurs, this could also explain the very different outcomes. In interviews with regulators, I have been told that both explanations played a role in why New York's involvement led to different results.
VII. Discussion

Although the sample size in this paper is admittedly small, the effect of prosecutor identity is large enough that its sign can still be convincingly established. The difference between the New York and non-New York settlements is of interest for multiple reasons. At the most basic level, by comparing settlement amounts with shareholder dilution, they complement the GAO (2005) review of the settlement negotiation process and answer an outstanding question from the accompanying Congressional hearing.

Beyond this, the apparent effect of New York’s involvement is jointly informative about the scope for prosecutorial discretion in these cases and about how New York and the SEC exercised it. Given what we already know anecdotally about New York's aggressiveness, particularly under Eliot Spitzer, that New York was more aggressive or more effectively aggressive than the SEC is perhaps not surprising. But it is arguably more surprising that New York's extra aggressiveness affected outcomes. Beyond a certain point, prosecutorial aggressiveness should not affect outcomes, since the constraint of what can be obtained in court will bind. The large estimated effect of New York's involvement implies that the SEC, when negotiating without New York, did not reach this level of aggressiveness, even in cases in which some had worried that the political environment would lead them to be overly aggressive.

The apparent difference in regulatory aggressiveness is consistent with the incentives created by regulators’ career concerns. As Reinganum (1981) argues, the optimality of allowing prosecutors discretion depends crucially on how their private incentives differ from maximizing social welfare. Both those who believe Eliot Spitzer’s political career concerns led him to be overly aggressive and those who worry that the
SEC staff’s career concerns lead them to take pro-industry positions can find some support for limits on discretion in these results. A simple policy reform that might limit both forms of discretion would be to make mandatory the calculation and public reporting of restitution ratios, perhaps using multiple methodologies if necessary.

Support in these results can also be found for the idea (Stigler, 1971; Macey, 1992) that single-industry regulators (like the SEC, particularly its Investment Management division) are less aggressive than those who regulate multiple industries (like state attorneys general), as they have staff who are more dependent on one industry for their next job. In contrast, the results do not seem consistent with the idea that the embarrassment of having under-regulated mutual fund valuation and trading before 2003 led the SEC to be overly aggressive in response. In fact, the low restitution ratios obtained by the SEC when negotiating without New York are all the more surprising given the visibility of these cases and the fact that in these cases, unlike many others handled by the SEC, there is publicly available data with which to assess the adequacy of settlements.

Finally, by sizing the economic consequences of exposure to regulation by an aggressive state attorney general, the paper can shed light on whether aggressive state regulation may have the unintended consequence of leading firms to decline to serve a state’s investors. Consider the following, admittedly extreme, thought experiment. Suppose that a non-New York headquarter mutual fund company had perfect foresight in 1998. In particular, it knew that a market timing case would be brought against it in 2003, and it knew that, given a five-year statute of limitations, it could avoid involvement by New York if simply declined all future mutual fund business from New York.
residents. Suppose also that it calculated from the data in Tables 6 and 7 that doing so would reduce its restitution and penalties from 19.5 basis points to 3.5 basis points of its total 2003 year-end assets. Against this 16 basis point savings, it would lose five years of expense ratio revenue for its New York residents. If we assume that this family’s expense ratio averages 75 basis points (the 2003 asset-weighted average in CRSP), that its marginal profit margin is twice an average post-tax profit margin of 20 percent (Huberman, 2006), and that New York accounts for 8 percent of its mutual fund assets, then exiting New York for 5 years would involve a marginal profit loss of 12 basis points of 1998-2003 average assets.

This suggests that, with perfect foresight, a mutual fund firm that knew it would be subject to a market timing case would have decided to not to serve New York customers, but only just. Unless one expects a scandal of the magnitude of 2003-4 to repeat itself every 5-10 years, then the profits to be gained in a large state like New York seem sufficient to keep an aggressive regulator from inducing exit. At the same time, the calculation is close enough that the conclusion will likely be different for a state that is significantly smaller or less wealthy than New York. This may help explain why New York can afford to be aggressive but also provide comfort to those who worry that 49 other state regulators will attempt to follow Mr. Spitzer’s example.

32 Assuming restitution and penalties are not tax deductible, the proper comparison is with post-tax profits. Huberman (2006) cites 35 percent pre-tax and 20 percent post-tax average profit margins as empirically reasonable. If marginal profit margins are double average, this would imply a pre-tax marginal profit margin of 70 percent or, equivalently, marginal costs of 22.5 basis points. This is roughly consistent with the cost function estimated for index funds in the working paper version of Hortascu and Syverson (2003).

In this table, and throughout the paper, standard errors are heteroskedasticity robust and significance at the 10, 5, and 1 percent level is indicated by 1, 2, and 3 asterisks, respectively. The unit of observation is a fund*fiscal year combination. For the beta regressions, the dependent variable is a Scholes-Williams (1977) beta estimated for each fund calendar year on the EAFE index using daily data and one lead and lag.

Data from CRSP include international equity funds (ICDI objective = international equity) for the calendar years 1999-2002. These are matched using tickers with Lipper data for the following fiscal year on fund share sales and redemptions and on dilution rates calculated from daily flow rates.

</tr>
</tbody>
</table>

Notes: Hausman tests do not reject the equivalence of OLS and IV or IV and IV (muni bond IV only). No p-value in these tests is smaller than 0.2. Of the 20 settlement firms, 3 have New York Headquarters and 9 offer single-state muni bond funds. For these 9, the average NY asset share is 0.15 with a standard deviation of 0.08. Standard errors are heteroskedasticity robust; significance at the 10, 5, and 1 percent level is indicated with 1, 2, and 3 asterisks, respectively.

Notes: Mutual fund assets "but for" the scandal are calculated by calculating what the assets of each fund would have been had they received the asset-weighted average percentage inflows for their category (S&P objective code) in each of the 12 months following disclosure of the SEC/State investigation. The value of lost assets is the difference between the "but for" and actual assets of surviving mutual funds, multiplied by a 4% valuation multiple (Pozen, 2002; Huberman, 2006). Dates of initial investigation disclosure is taken from Table I of Hogue and Wellman (2005).
